ANDERSON, N. H., AND K. W. CUMMINS. 1979. Influences of diet on the life histories of aquatic insects. *J. Fish. Res. Board Can.* 36: 335-342.

Benthic species are partitioned into functional feeding groups based on food-acquiring mechanisms. Effects of food quality on voltinism, growth rate, and size at maturity are demonstrated for representatives of gougers and shredders, collectors, and scrapers. Food quality for predators is uniformly high, but food quantity (prey density) obviously influences their life histories. A food switch from herbivory to predation, or some ingestion of animal tissues, in the later stages is a feature of the life cycle of many aquatic insects. Temperature interacts with both food quality and quantity in effects on growth as well as having a direct effect on control of metabolism. Thus further elaboration of the role of food in life history phenomena will require controlled field or laboratory studies to partition the effects of temperature and food.

Key words: aquatic insects, feeding strategies, functional groups, life histories

ANDERSON, N. H., AND K. W. CUMMINS. 1979. Influences of diet on the life histories of aquatic insects. *J. Fish. Res. Board Can.* 36: 335-342.

Nous avons séparé les espèces benthiques en groupes, selon le type d'alimentation fonctionnelle fondé sur les mécanismes d'acquisition de la nourriture. Chez des représentants de creuseurs et de déchireurs, de collecteurs et de racleurs, nous démontrons les effets de la qualité de la nourriture sur le voltinisme, le rythme de croissance et la taille à la maturité. Pour les prédateurs, la qualité de la nourriture est uniformément haute, mais la quantité de nourriture (densité des proies) influe évidemment sur leurs cycles biologiques. Un changement de régime, d'herbivore à prédateur, ou une certaine absorption de tissus animaux aux stades ultérieurs est une caractéristique du cycle biologique de plusieurs insectes aquatiques. Il y a interaction de la température avec la qualité aussi bien que la quantité de nourriture dans ses effets sur la croissance, de même qu'un effet direct sur le contrôle du métabolisme. Des études plus poussées sur le rôle de la nourriture dans les phénomènes du cycle biologique nécessiteront des expériences de laboratoire ou des études contrôlées sur le terrain afin de séparer les effets de la température et de la nourriture.

Accepté le 14 décembre 1978

THE study of trophic relations in freshwater communities reveals a bewildering array of foods available and methods of resource utilization. As Hynes (1970, p. 192) suggested "It may seem inappropriate to consider the food of invertebrates in any biotope, as it is obviously as varied as the invertebrates themselves." Because of such complexity, it seems necessary to attempt some simplification in evaluating the general role of nutrition in controlling aquatic insect life histories — primarily growth (i.e. rate and maximum size attained). The stereotyping of food habits, based on what is eaten, at the generic or family level for aquatic

insects has been criticized (e.g. Resh 1976; Fuller and Stewart 1977). However, the partitioning of taxa on the basis of food-acquiring mechanisms, that is, community functional role, rather than what is eaten, has proven useful in approaching certain ecological questions (Cummins 1973, 1974; Merritt and Cummins 1978; Wiggins and Mackay 1978). This approach, which stresses partitioning of food resources on a community basis, reveals that detrital utilization by shredders (coarse particle feeders) and collectors (fine particle feeders) dominates most forested headwater streams. This is in contrast to many terrestrial systems in which the insects feed primarily on living plant tissue.

Various aspects of food (diet) as a factor influencing life histories, or life history strategies, are examined. Since field data implicating food as a causal factor usually have other possible explanations, our task is akin to completing a jigsaw puzzle with most of the pieces missing. Furthermore, the interaction of abiotic factors, especially temperature, with food quality and quantity (food per unit of environment) confounds the

¹Paper presented at the Plenary Session of the 26th Annual Meeting of the American Benthological Society held at Winnipeg, Man., May 10-12, 1978.

²Technical Paper No. 4875, Oregon Agricultural Experiment Station, and Contribution No. 322 of the Coniferous Forest Biome, Ecosystems Analysis Studies, U.S. International Biological Program.

tive correlation between selective feeding and density of microbial flora (Bärlocher and Kendrick 1973a, b), nitrogen content (Iversen 1974), and respiration rate and ATP content per unit weight of leaf (M. Ward, R. Speaker, and K. Cummins unpublished data). Thus, the rate of leaf degradation (e.g. *Alnus*, *Tilia*, *Fraxinus*, fast; *Carya*, intermediate; *Quercus*, *Fagus* and conifers, slow) is a good predictor of shredder feeding preference.

3. Although shredders selectively feed on the best conditioned substrate, they can make an adjustment in feeding rate to maintain their growth rate.

FOOD QUALITY OF *Alnus* LEAVES FOR *Clistoronia magnifica*

Compared with many common riparian species, *Alnus* leaves are high in nitrogen, rapidly conditioned, and one of the most palatable species for benthic invertebrates (Iversen 1974; Otto 1974; Petersen and Cummins 1974; Anderson and Grafius 1975). Therefore, alder leaves have been used as a standard for comparison in short-term growth studies of various Trichoptera at Oregon State University. However, when the limnephilid *C. magnifica* was reared through the entire larval stage and compared with field collected specimens, it became apparent that laboratory-conditioned alder leaves were inadequate to produce normal growth. A diet including a supplement of wheat grains or enchytraeid worms in addition to alder leaves has enabled continuous rearing of *C. magnifica* (Anderson 1976, 1978). Feeding experiments with individuals from the laboratory culture indicate that development time was at least 10 wk longer and mortality more than twice as high on alder leaves compared with a supplemented diet (Fig. 3). Mean pupal weight was only 22.65 (± 1.04) mg on the nonsupplemented diet as compared with 37.90 (± 2.32) mg on the leaves plus supplement.

Laboratory-conditioned leaves were compared as food with leaves incubated in a stream to test the possibility that an inferior microbial flora developed on laboratory-conditioned leaves. Conditioning time was 2–3 wk at 12–15°C in the field and at 15°C in the laboratory. Fecal production was greater with the stream-conditioned leaves than for the laboratory-conditioned leaves (Table 1), which suggests that the former were more palatable. On the evidence of their development to fifth instar and on final weights, larvae fed on field-conditioned leaves were judged to be marginally more advanced than those fed on laboratory-conditioned leaves. However, the differences in weights are not significant ($P > .05$), and both are markedly below the weights of larvae receiving a wheat supplement. Low fecal production by control larvae is attributed to higher assimilation of the wheat diet. Thus, laboratory conditioning is apparently not a major factor in reduced growth rates on the nonsupplemented detritus diet.

FIG. 3. Rate of development and survival of *Clistoronia magnifica* larvae reared on *Alnus* leaves compared with a control of *Alnus* plus a supplement of wheat grains and enchytraeid worms. Both series reared at 15°C, with conifer needles and sand for case material.

Higher quality food is required during the final instar when growth is rapid and fat reserves are being laid down prior to pupation. A series of 26 *C. magnifica* larvae that had been reared from week 12 to 17 on alder leaves were split into two groups after 50% of the individuals had molted to the final instar. One group was continued on alder leaves while the other received leaves and a supplement of wheat plus worms. Mean time to pupation was a further 17 wk for the alder group as opposed to only 7 wk for those that received the supplement. Even more striking were the differences in survival and pupal weight: alder, ($n = 4$), $\bar{x} = 15.0$ mg; supplement ($n = 11$), $\bar{x} = 39.8$ mg. Pupae from the stock culture (fed a supplement diet) averaged 40.1 mg. Thus, the addition of the supplement for the final 5–7 wk of the larval stage provided sufficient nutriment to allow normal weight to be regained.

FOOD QUALITY OF BASSWOOD (*Tilia*) AND HICKORY (*Carya*) LEAVES FOR *Tipula abdominalis*

Recent work at the Kellogg Biological Station (M. Ward, R. Speaker, and K. Cummins unpublished data) has shown that the shredder, *T. abdominalis*, can increase its feeding rate to compensate for poor food quality and thus maintain a typical growth rate. Two levels of food quality were obtained by using hickory and basswood leaves. These were incubated with natural stream microorganisms for 9 wk at 10°C. Respiration rates were 30% higher for the basswood leaves, indicating greater microbial conditioning than for hickory and, consequently, a higher food quality. *Tipula abdominalis* larvae grew at the same rate in a 1-wk experiment when fed either type of leaf separately. The weight loss of the hickory leaves was about 30% greater than the basswood, but the efficiency of food

TABLE 1. Growth, development, and fecal production of *Clistoronia magnifica* larvae reared on laboratory-conditioned *Alnus* leaves ($n = 40$), field-conditioned *Alnus* leaves ($n = 40$), and a control of leaves plus wheat grains ($n = 20$). Larvae reared for 18 d at 15°C.

^a95% confidence interval.

conversion to growth (relative growth rate/consumption) (Waldbauer 1968) for *T. abdominalis* larvae on basswood was twice that on hickory. That is, the larvae ingested hickory leaves more rapidly, compensating for the lower food quality.

Feeding by *T. abdominalis* larvae was minimal on both basswood and hickory leaves when the conditioning time was reduced to 2 or 3 wk. With only this type of food available many of the larvae attempted to crawl out of the experimental chambers and those that remained did not grow.

The compensatory effect of food quality in overriding direct temperature effects on shredder growth is shown in Table 2. Basswood leaves conditioned at 5°C were of higher quality than hickory leaves at 10°C. When expressed per unit of temperature time (degree days), the growth rates of *T. abdominalis* and the caddisfly *Pycnopsyche guttifer* were higher on basswood than on hickory leaves.

The above experiments suggest that the overall shredder feeding strategy is selection of the highest quality (greatest microbial biomass) food available in a given leaf accumulation, increased feeding rate if the best available is not of sufficient quality to maintain growth in the normal range, and emigration if quality or quantity is below some minimal level. Temperature control of the general metabolic rate of shredders is compensated to some extent by the temperature-mediated effects on food quality. In addition, as demonstrated for *C. magnifica* (Anderson 1976), some intake

of high protein (animal) food may be required for individuals to achieve an appropriate mature weight.

Collectors

In contrast to shredders that feed on CPOM that is colonized by microbes both on the surface and throughout the matrix, collectors utilize fine particulate organic matter (FPOM) that is primarily surface-colonized by bacteria. The sources of FPOM food and its nutritional quality varies considerably. Much of it is fecal material produced by shredders and other functional groups that is recycled or "spiralled" (Wallace et al. 1977) by the stream biota. Other sources are wood and leaf fragments produced by physical abrasion and microbial maceration, senescent periphytic algae, planktonic algae, aquatic macrophyte fragments, small animals, and particles formed by the flocculation of dissolved organic matter. The organic layer on stones, described by Madsen (1972) as a matrix of bacteria, extracellular material, fungi, and organic and inorganic particles, may be used by collectors or by scrapers (see below).

Black fly larvae typify collectors that filter FPOM from the water column. Gut filling times are about 20–30 min (Ladle et al. 1972). Since the food is passed so rapidly, the nutritional value is probably derived by stripping bacteria from the refractory detritus particles. Carlsson et al. (1977) have documented a relationship between the type of food available and the life cycle of some Lapland black flies. The larvae at lake outfalls occur in denser aggregations and have faster growth than the same or other species occurring further downstream. Phytoplankton and coarse detritus ($> 2 \mu\text{m}$) occurred in similar amounts in all reaches, so they concluded that small particles, from $2 \mu\text{m}$ down to colloidal size, were the resource that maintained the huge larval aggregations at the lake outlet. This material is produced by decomposition on the lake bottom in winter and is washed into the river during ice melt.

The influence of food quality, as indicated by particle-associated respiration rate or ATP content, on the growth of the collector-gatherer midge, *Paratendipes albimanus*, is shown in Fig. 4 and 5. All food materials were wet sieved to the same particle size range before use. The oak and hickory leaves had been conditioned

Hickory	10	282	0.27	0.013	3.51	0.348	5.19	0.515

^aThe factoring out of temperature in these calculations assumes that growth is very low at 0°C.

FIG. 4. Relative growth rate (Waldbauer 1968) of *Paratendipes albimanus* fed four diets (all sieved to the same particle size) compared at three temperatures (10, 15, 20°C) on the basis of substrate respiration rate ($\mu\text{LO}_2 \cdot \text{mg AFDW}^{-1} \cdot \text{h}^{-1} \cdot ^\circ\text{C}^{-1}$). Modified from Ward and Cummins (1978).

in aerated batch cultures with aquatic hyphomycete fungi inocula for 2 wk. The leaves were dried, ground, and wet sieved to the appropriate size range. The experiments were conducted at three temperatures (10, 15, and 20°C). Each of the three points for each food type represents a temperature in Fig. 4 and 5. Although in all cases the higher temperature produced the highest growth rate on a given food, it is clear that food quality outweighed the direct effect of temperature on larval growth.

Scrapers

This functional group is typified by glossosomatid caddisflies, representatives of the baetid, heptageniid, and ephemerellid mayflies, and psephenid beetle larvae (Merritt and Cummins 1978). Scrapers are dependent primarily on autochthonous production as a food resource but their mode of feeding also results in ingestion of detritus, as well as the organic layer on stones (Madsen 1972). The nutritional content of live algal cells is high; Cummins and Wuycheck (1971) report differences of several hundred calories per gram between diatoms and detritus.

Previous studies indicated that *Glossosoma nigrior* from first-order streams were much smaller than those in a third-order stream (Cummins 1973, 1975). Gut content analysis revealed that larvae in the small stream consumed more detritus whereas those in the third-order stream fed predominantly on diatoms. The inter-

FIG. 5. Relative growth rate of *Paratendipes albimanus* fed four diets compared with substrate ATP content as an index of microbial biomass ($\mu\text{M ATP/mg AFDW}$). See Fig. 4 caption for additional details.

action of temperature and food on growth of *G. nigrior* is shown in Table 3. The ratio of gross primary production to community respiration (P/R) is a reflection of the available algal food, and the data indicate a strong relationship between P/R and the final larval (prepupal) weights.

As shown by Gose (1970), the amount of accumulated temperature can influence the number of generations of a scraper species, and it probably affects the maximum size attained by individuals in a given cohort. There was a 20% greater accumulation of day degrees in the third-order stream, which is undoubtedly a con-

and duration of larval growth to the extent that adult size is significantly reduced. Thus, in any study of growth, it is important to separate as far as possible the direct (animal metabolism) and indirect (food quality and quantity) effects of temperature.

Benthic Life Histories: Summary and Future Needs^{1,2}

T. F. WATERS

Department of Entomology, Fisheries and Wildlife, University of Minnesota, St. Paul, MN 55108, USA

WATERS, T. F. 1979. Benthic life histories: summary and future needs. J. Fish. Res. Board Can. 36: 342-345.

The symposium indicated many ways in which greater knowledge of benthic life histories can be used to develop and improve techniques such as sampling, taxonomic methods, and bioassays. Benthic organisms' diet and physical environment, factors variable in nature, were shown to be capable of modifying certain life history features such as growth rate and voltinism. The lack of accumulated life history data and the need to tailor sampling schedules to life history events were commonly identified elements in the symposium. Future research needs included (1) basic data on benthic life history, (2) improved taxonomy of immature benthic invertebrates, and (3) understanding the entire life history of an organism in relation to the seasonal progression of its environment. Management implications of benthic life history information included more applicable data from long-term bioassays on all life history stages, and improved management of stream fisheries through habitat alteration to manipulate benthic production.

Key words: life history, benthos, symposium

WATERS, T. F. 1979. Benthic life histories: summary and future needs. J. Fish. Res. Board Can. 36: 342-345.

Au cours du colloque, on a indiqué plusieurs façons d'utiliser de meilleures informations sur le cycle biologique d'organismes benthiques afin de mettre au point et améliorer les techniques telles que l'échantillonnage, les méthodes taxonomiques et les analyses biologiques. On a démontré que le régime alimentaire et le milieu physique des organismes benthiques, facteurs variables dans la nature, peuvent modifier certaines caractéristiques du cycle biologique, telles que le rythme de croissance et le voltinisme. Parmi les points communément identifiés au cours du colloque, on note le manque de données accumulées sur les cycles biologiques et le besoin d'échelonner l'échantillonnage selon les événements de ces cycles. Parmi les besoins futurs en recherche, on compte: (1) les données de base sur le cycle biologique benthique, (2) une taxonomie améliorée des invertébrés benthiques immatures et (3) la compréhension du cycle biologique complet d'un organisme en relation avec l'évolution saisonnière de son milieu. Pour ce qui est de la manière dont les gestionnaires peuvent utiliser les connaissances sur les cycles biologiques benthiques, on note des résultats plus facilement applicables d'analyses biologiques à long terme sur tous les stades du cycle biologique. On note aussi une meilleure gestion des pêches fluviales par altération de l'habitat et manipulation de la production de benthos.
